

Lecture #15: OOP

Public Service Announcement: Hackers@Berkeley will be hosting a HackJam this Saturday—

- Low-pressure hackathon for both experienced makers and newbies.
- Work together, eat food, and
- Hack something together in just 12 hours.
- Workshops to help you make something cool.
- Judges, prizes, and most importantly - food.
- RSVP by joining the Facebook event page:

<https://www.facebook.com/events/1448019312098352/>

Guerrilla Section #2: Extra groupwork-based section on mastering Recursion. Sunday (March 2nd) at 4pm in 271 Soda (cardkey entry). Check Piazza for details.

Extending the Mutable Objects: Classes

- We've seen a variety of builtin mutable types (sets, dicts, lists).
- ... And a general way of constructing new ones (functions referencing nonlocal variables).
- But in actual practice, we use a different way to construct new types—syntax that leads to clearer programs that are more convenient to read and maintain.
- The Python **class** statement defines new classes or types, creating new, vaguely dictionary-like varieties of object.

Simple Classes: Bank Account

```
class Account: # Type name
    # constructor method
    def __init__(self, initial_balance):
        self._balance = initial_balance

    def balance(self): # instance method
        return self._balance # instance variable

    def deposit(self, amount):
        if amount < 0:
            raise ValueError("negative deposit")
        self._balance += amount

    def withdraw(self, amount):
        if 0 <= amount <= self._balance:
            self._balance -= amount
        else: raise ValueError("bad withdrawal")
```

```
>>> mine = Account(1000)
>>> mine.deposit(100)
>>> mine.balance()
1100
>>> mine.withdraw(200)
>>> mine.balance()
900
```

Class Concepts

- Classes beget *instances*, created by “calling” the class: `Account(1000)`.
- Each such `Account` object (instance) contains *attributes*, accessed using `object.attribute` notation.
- The *defs* inside classes define function-valued attributes called *methods* (full names: `Account.balance`, etc.) Each object has a copy.
- A call `mine.deposit(100)` is essentially `Account.deposit(mine, 100)`.
- By convention, we therefore call the first argument of a method something like “self” to indicate that it is the object from which we got the method.
- When an object is created, the special `__init__` method is called first.
- Each `Account` object has other attributes (`_balance`), which we create by assignment, again using dot notation.

Philosophy

- Just as **def** defines functions and allows us to extend Python with new operations, **class** defines types and allows us to extend Python with new kinds of data.
- What do we want out of a class?
 - A way of defining named *new types* of data.
 - A means of defining and accessing *state* for these objects.
 - A means of defining and using *operations* specific to these objects.
 - In particular, an operation for *initializing* the state of an object.
 - A means of *creating* new objects.

Applied Philosophy

- The Account type illustrates how we do each of these

<code>class Account:</code>	Define named new type
<code> def __init__(self, initial_balance):</code>	How to initialize
<code> self._balance = initial_balance</code>	Create/modify state
<code> def balance(self):</code>	Define new operation on Accounts
<code> return self._balance</code>	Access state of an Account
<code> ...</code>	
<code>myAccount = Account(1000)</code>	Create a new Account object,
<code>print(myAccount.balance())</code>	Operate on an Account object.

Class Attributes

- Things like `_balance`, `__init__`, and `deposit` are attributes of *instances of classes*.
- Sometimes, a quantity applies to a class type as a whole, not a specific instance.
- For example, with `Accounts`, you might want to keep track of the total amount deposited from all `Accounts`.
- This is an example of a *class attribute*.

Class Attributes in Python

```
class Account:
    _total_deposits = 0      # Define/initialize a class attribute
    def __init__(self, initial_balance):
        self._balance = initial_balance
        Account._total_deposits += initial_balance # Use the class name
    def deposit(self, amount):
        self._balance += amount
        Account._total_deposits += amount

    @staticmethod
    def total_deposits():    # Define a class method.
        return Account._total_deposits
```

```
>>> acct1 = Account(1000)
>>> acct2 = Account(10000)
>>> acct1.deposit(300)
>>> Account.total_deposits()
11300
>>> acct1.total_deposits()
11300
```

Modeling Attributes in Python

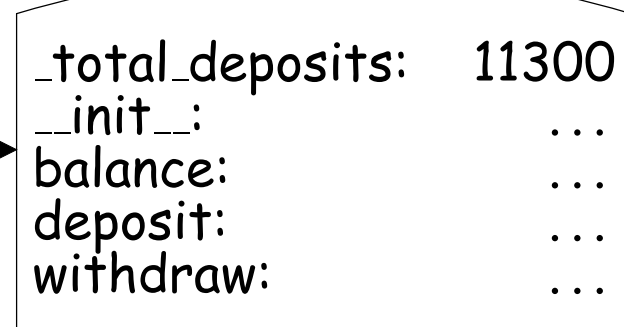

- Unlike C++ or Java, Python takes a very dynamic approach.
- Classes and class instances behave rather like environment frames.

```
def Account:  
    _total_deposits = 0
```

```
def __init__(...):  
    self._balance = ...  
    Account._total_deposits = ...
```

```
acct1 = Account(1000)  
acct2 = Account(10000)  
acct1.deposit(300)
```

Account:

acct1:

acct2:

- Curved boxes are objects.
- Flat-bottomed boxes are class objects.
- 'x.y': look for 'y' starting at 'x'

Assigning to Attributes

- Assigning to an attribute of an object (including a class) is like assigning to a local variable: it creates a new binding for that attribute in the object selected from (i.e., referenced by the expression on the left of the dot).

```
>>> def Value:
...     value = 0
...
>>> val1 = Value()
>>> val2 = Value()
>>> val2.value = 3
>>> val1.value
0
>>> Value.value
0
>>> val2.value
3
```

Methods

- Consider

```
>>> def Foo:
...     def set(self, x):
...         self.value = x
>>> aFoo = Foo()
>>> aFoo.set(13)  # The first parameter of set is aFoo.
>>> aFoo.value
13
>>> aFoo.set
<bound method Foo.set of ...>
```

- Selection of attributes from objects (other than classes) that were defined as functions in the class does something to those attributes so that they take one fewer parameters: first parameter is *bound to* the selected-from object.
- Effect of selecting `aFoo.set` is like calling `partial_bind(aFoo, Foo.set)`, where

```
def partial_bind(obj, func): return lambda x: func(obj, x)
```
