### Lecture #16: Inheritance and Interfaces

#### Inheritance

- Classes are often conceptually related, sharing operations and behavior
- One important relation is the subtype or "is-a" relation.
- Examples: A car is a vehicle. A square is a plane geometric figure.
- When multiple types of object are related like this, one can often
  define operations that will work on all of them, with each type adjusting the operation appropriately.
- In Python (like C++ and Java), language mechanisms called *inheritance* and *dynamic method selection* accomplish this.

## Example: Geometric Plane Figures

- Want to define a collection of types that represent polygons (squares, trapezoids, etc.).
- First, what are the common characteristics that make sense for all polygons?

```
class Polygon:
    def is_simple(self):
        """True iff I am simple (non-intersecting)."""
    def area(self): ...
    def bbox(self):
        """(xlow, ylow, xhigh, yhigh) of bounding rectangle."""
    def num_sides(self): ...
    def vertices(self):
        """My vertices, ordered clockwise, as a sequence
        of (x, y) pairs."""
    def describe(self):
        """A string describing me."""
```

• The point here is mostly to document our concept of Polygon, since we don't know how to implement any of these in general.

Last modified: Wed Mar 5 12:09:49 2014 CS61A: Lecture #16 3

## Partial Implementations

Even though we don't know anything about Polygons, we can give default implementations.

```
class Polygon:
    def is_simple(self): raise NotImplemented # (see next slide)
    def area(self): raise NotImplemented
    def vertices(self): raise NotImplemented
    def bbox(self):
        V = self.vertices()
        xlow, ylow = xhigh, yhigh = V[0]
        for x, y in V[1:]:
            xlow, ylow = min(x, xlow), min(y, ylow),
            xhigh, yhigh = max(x, xhigh), max(y, yhigh),
        return xlow, ylow, xhigh, yhigh
    def num_sides(self): return len(self.vertices())
    def describe(self):
        return "A polygon with vertices {0}".format(self.vertices())
```

CS61A: Lecture #16 4

#### Quick Aside: raise

- The statement raise NotImplemented is said to raise an exception.
- Usually used to signal an error ("exceptional condition").
- But sometimes used for regular programming (iterators later in this lecture).
- In place of NotImplemented, can use any subtype of the built-in class BaseException.
- And now, back to Polygons.

#### Specializing Polygons

 At this point, we can introduce simple (non-intersecting) polygons, for which there is a simple area formula.

```
class SimplePolygon(Polygon):
    def is_simple(self): return True
    def area(self):
        a = 0.0
        V = self.vertices()
        for i in range(len(V)-1):
              a += V[i][0] * V[i+1][1] - V[i+1][0]*V[i][1]
        return -0.5 * a
```

- This says that a SimplePolygon is a kind of Polygon, and that the attributes of Polygon are to be *inherited* by simple Polygon.
- So far, none of these Polygons are much good, since they have no defined vertices.
- We say that Polygon and SimplePolygon are abstract types.

### A Concrete Type

• Finally, a square is a type of simple Polygon:

- Don't have to define area,, etc., since the defaults work.
- We chose to override describe to give a more specific description.

#### Inheritance Explained

• Inheritance (in Python) works like nested environment frames.

CS61A: Lecture #16 8

# Using Base Types

- Sometimes, we want an overriding method in a subtype to augment rather than totally replace an existing method.
- That means that we have to call the original version of the method within the overriding method somehow.
- Can't just do an ordinary method call on self, since that would cause infinite recursion.
- Fortunately, we can explicitly ask for the original version of the method by selecting from the class.

CS61A: Lecture #16 9

# Example: "Memoization"

• Suppose we have

```
class Evaluator:
    def value(self, x):
        some expensive computation that depends only on x

class FastEvaluator(Evaluator):
    def __init__(self):
        self.__memo_table = {} # Maps arguments to results

def value(self, x):
    """A memoized value computation"""
    if x not in self.__memo_table:
        self.__memo_table[x] = Evaluator.value(self, x)
    return self.__memo_table[x]
```

- FastEvaluator.value must call the .value method of its base (super) class, but we can't just say self.value(x), since that gives an infinite recursion.
- So we search for .value starting in Evaluator, as plain function.

Last modified: Wed Mar 5 12:09:49 2014

CS61A: Lecture #16 10

#### super()

- Usually, when (as in FastEvaluator) we want to call a method we are overriding, we want to clearly mark this fact.
- So, the usual way to write FastEvaluator is like this:

```
class FastEvaluator(Evaluator):
    def __init__(self):
        self.__memo_table = {} # Maps arguments to results

def value(self, x):
    """A memoized value computation"""
    if x not in self.__memo_table:
        self.__memo_table[x] = super().value(x)
    return self.__memo_table[x]
```

#### Generic Programming

• Consider the function find:

- This same function works on lists, tuples, strings, and (if the keys are consecutive integers) dicts.
- In fact, it works for any list L for which len and indexing work as they do for lists and tuples.
- That is, find is generic in the type of L.

#### The Idea of an Interface

• In Python, this means any type that fits the following interface:

```
class SequenceLike:
    def __len__(self):
        """My length, as a non-negative integer."""

def __getitem__(self, k):
        """My kth element, where 0 <= k < self.__len__()"""</pre>
```

(for which len(L) and L[...] are "syntactic sugar.")

- This is one way to describe an interface, which in a programming language consists of
  - A syntactic specification (operation names, numbers of parameters), and
  - A semantic specification—its meaning or behavior (given here by English-language comments.)
- Generic functions are written assuming only that their inputs honor particular interfaces.
- The fewer the assumptions in those interfaces, therefore, the more general (and reusable) the function.

#### Supertypes as Interfaces

- We call the types that a Python class inherits from its *supertypes* or *base types* (and the defined class, therefore, is a *subtype*).
- Good programming practice requires that we treat our supertypes as interfaces, and adhere to them in the subtypes.
- For example, were we to write

```
class MyQueue(SequenceLike):
    def __len__(self): ...
    def __getitem__(self, k): ...
```

then good practice says that MyQueue.\_len\_ should take a single parameter and return a non-negative integer, and that MyQueue.\_getitem\_ should accept an integer between 0 and the value of self.\_len\_()

- Python doesn't actually enforce either of these provisions; it's up to programmers to do so.
- Other languages (like C++, Java, or Ada) enforce the syntactic part of the specification.

### **Duck Typing**

- A statically typed language (such as Java) requires that you specify a type for each variable or parameter, one that specifies all the operations you intend to use on that variable or parameter.
- To create a generic function, therefore, your parameters' types must be subtypes of some particular interface.
- You can do this in Python, too, but it is not a requirement.
- In fact, our find function will work on any object that responds appropriately to \_len\_ and \_getitem\_, regardless of the object's type.
- This property is sometimes called duck typing: "This parameter must be a duck, and if it walks like a duck and quacks like a duck, we'll say it is a duck."
- In sum, an explicit supertype is not required in Python to get the benefits of generic programming, but it can help document what we're doing.

## Consequences of Good Practice

- If we obey the supertype-as-interface guideline, then we can pass any object that has a subtype of SequenceLike to find and expect it to work.
- This fact is an example of what is called the Liskov Substitution Principle, after Prof. Barbara Liskov of MIT, who is generally credited with enunciating it.

#### Interface as Documentation

- The interface (especially its documentation comments) provides a contract between clients of the interface and its subtypes—implementations of the interface:
  - "I, the implementor, agree that all the subclasses I define will conform to the signature and comments in this interface, as long as you, the client, obey any restrictions specified in the interface."
- Since Python does not check or enforce the consistency of supertypes and subtypes, use of the guideline is a matter of individual discipline.
- Enforced or not, the interface type provides a convenient place to document the contract.
- But even when using duck typing, good practice requires that we document the assumptions made by the implementor about parameters to methods (what methods they have, in particular).

# Example: The \_repr\_ Method

- When the interpreter prints the value of an expression, it must first convert that value to a (printable) string.
- To do so, it calls the <u>repr</u>() method of the value, which is supposed to return a string that suggests how you'd create the value in Python.

```
>>> "Hello"
'Hello'
>>> print(repr("Hello"))
'Hello'
>>> repr("Hello") # What does the interpreter print?
```

- (As a convenience, the built-in function repr(x) calls x.\_repr\_.)
- User-defined classes can define their own \_repr\_ method to control how the interpreter prints them (see HW#6).

 Last modified: Wed Mar 5 12:09:49 2014 CS61A: Lecture #16 18

# Example: The \_str\_ Method

- When the print function prints a value, it calls the <u>\_str\_()</u> method to find out what string to print.
- $\bullet$  The constructor for the string type, str, does the same thing.
- Again, you can define your own <u>str</u> on a class to control this behavior. (The default is just to call <u>repr</u>)

```
>>> class rational:
...          def __init__(num, den): ...
...          def __str__(self):
...          if self.numer() == 0: return "0"
...          elif self.denom() == 1: return str(self.numer())
...          else: return "{0}/{1}".format(self.numer(), self.denom())
...
>>> rational(3,4)
3/4
>>> rational(5, 1)
5
```
